- Complexity analysis 1
- Styles of algorithms 1
- List implementations 1
- Sorting (lists) 3
- Searching (in (sorted) lists) 4
- Hashing (to manage lists) 2
- Trees (to manage lists) 4
- Graphs (no lists!) 5
- Sum **~9/25**

# Topics of Next Lessons

---

- **Search:** Given a (sorted or unsorted) list  $A$  with  $|A|=n$  elements (integers). Check whether a given **value  $c$  is contained in  $A$**  or not
  - Search returns true or false
  - If  $A$  is sorted, we can exploit transitivity of " $\leq$ " relation
  - Fundamental problem with a zillion applications
- **Select:** Given an unsorted list  $A$  with  $|A|=n$  elements (integers). Return the  **$i$ 'th largest element of  $A$** .
  - Returns an element of  $A$
  - The sorted case is trivial – return  $A[i]$
  - Interesting problem (especially for median) with some applications
  - [Interesting proof]

# Searching in an Unsorted List

---

- No magic
- Compare  $c$  to every element of  $A$
- Worst case ( $c \notin A$ ):  $O(n)$
- Average case ( $c \in A$ )

- If  $c$  is at position  $i$ , we require  $i$  tests
- All positions are equally likely: probability  $1/n$

- This gives

$$\frac{1}{n} \sum_{i=1}^n i = \frac{1}{n} * \frac{n^2 + n}{2} = \frac{n+1}{2} = O(n)$$

```
1. A: unsorted_int_array;
2. c: int;
3. for i := 1.. |A| do
4.   if A[i]=c then
5.     return true;
6.   end if;
7. end for;
8. return false;
```

- Sequential access: Same for array, linked lists, ...

# Binary Search (binsearch)

- If A is sorted, we can be much faster
- Binary Search: Exploit **transitivity**

# Recursive versus Iterative Binsearch

---

- Recursive binsearch uses only end-recursion
- Equivalent **iterative program** is more space-efficient
  - We don't need old values for  $l, r$  – no call stack
  - $O(1)$  additional space

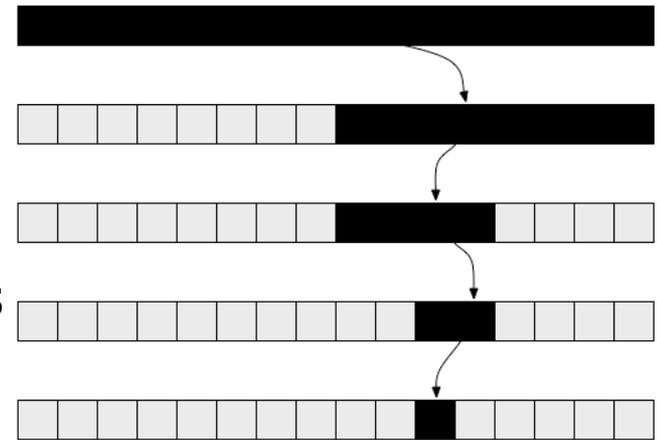

```
1. func bool binsearch(A: sorted_array;  
                      c, f, r : int) {  
2.   If f>r then  
3.     return false;  
4.   end if;  
5.   m := f+((r-f) div 2);  
6.   If c<A[m] then  
7.     return binsearch(A, c, f, m-1);  
8.   else if c>A[m] then  
9.     return binsearch(A, c, m+1, r);  
10.  else  
11.    return true;  
12.  end if;  
13. }
```

```
1. A: sorted_int_array;  
2. c: int;  
3. f := 1;  
4. r := |A|;  
5. while f≤r do  
6.   m := f+(r-f) div 2;  
7.   if c<A[m] then  
8.     r := m-1;  
9.   else if c>A[m] then  
10.    f := m+1;  
11.  else  
12.    return true;  
13. end while,  
14. return false;
```

# Complexity of Binsearch

---

- In every call to binsearch (or every while-loop), we only do constant work
  - Independent of  $n$
- With every call, we reduce the size of sub-array by 50%
  - We call binsearch once with  $n$ , with  $n/2$ , with  $n/4$ , ...
- Binsearch has worst-case complexity  $O(\log(n))$
- Average case only marginally better
  - We only stop if we find  $c$  before the interval has size 1
  - Chances to “hit” target in the middle of the search is low for (many) first steps
  - Chances increase for (few) last steps
  - See Ottmann/Widmayer

# Searching without Divisions

---

- Can we search in  $O(\log(n))$  without complex arithmetic?
  - Simple arithmetic operations are faster on real hardware
  - But: Binsearch usually uses bit shift (div 2) – **very fast**
- **Fibonacci search:**  $O(\log(n))$  without division/multiplication
  - Also interesting:  $O(\log(n))$  without the “always 50%” pattern
- Recall **Fibonacci numbers**
  - $\text{fib}(1)=\text{fib}(2)=1; \text{fib}(i)=\text{fib}(i-1)+\text{fib}(i-2)$
  - 1, 1, 2, 3, 5, 8, 13, 21, 34, ...
  - Observation:  $\text{fib}(i-2)$  is roughly  $1/3$ ,  $\text{fib}(i-1)$  roughly  $2/3$  of  $\text{fib}(i)$

# Fibonacci Search: Idea

- Let  $\text{fib}(i)$  be the smallest fib-number with  $\text{fib}(i) \geq |A|$
- If  $A[\text{fib}(i-2)] = c$ : stop
- Otherwise, search in  $[1 \dots \text{fib}(i-2)]$  or  $[\text{fib}(i-2)+1 \dots n]$
- Beware **out-of-range part**  $A[n+1 \dots \text{fib}(i)]$
- No divisions

# Algorithm (assume $|A| = \text{fib}(i) - 1$ )

- 3-6: Search at  $A[\text{fib}(i-2)]$ 
  - With  $\text{fib}_2, \text{fib}_3$  we can compute **all other fib's**
  - $\text{fib}(i) = \text{fib}(i-1) + \text{fib}(i-2)$
  - $\text{fib}(i-1) = \text{fib}(i-2) + \text{fib}(i-3)$
  - ...
- 7-24: Partition A at descending Fibonacci numbers
- After each comparison, **update  $\text{fib}_3$  and  $\text{fib}_2$**

```
1. A: sorted_int_array;
2. c: int;
3. compute i; #smallest fib(i)>|A|
4. fib3 := fib(i-3); # Precomputed
5. fib2 := fib(i-2); # Precomputed
6. m := fib2;
7. repeat
8.   if c>A[m] then
9.     if fib3=0 then return false
10.    else
11.      m := m+fib3;
12.      tmp := fib3;
13.      fib3 := fib2-fib3;
14.      fib2 := tmp;
15.    end if;
16.  else if c<A[m]
17.    if fib2=1 then return false
18.    else
19.      m := m-fib3;
20.      fib2 := fib2 - fib3;
21.      fib3 := fib3 - fib2;
22.    end if;
23.  else return true;
24. until true;
```

# Example (recall: 1,1,2,3,5,...)

Search 3 in  
{1,2,3};  
i=5

fib2	fib3	m
2	1	2
1	1	3

true

Search 6 in  
{1,2,3,4};  
i=5

fib2	fib3	m
2	1	2
1	1	3
1	0	4

false

Search 100 in  
{1...10000}

fib2	fib3	m
4181	2584	4181
1597	987	1597
...	...	...

```
1. A: sorted_int_array;  
2. c: int;  
3. compute i; #smallest fib(i)>|A|  
4. fib3 := fib(i-3);  
5. fib2 := fib(i-2);  
6. m := fib2;  
7. repeat  
8.   if c>A[m] then  
9.     if fib3=0 then return false  
10.    else  
11.      m := m+fib3;  
12.      tmp := fib3;  
13.      fib3 := fib2-fib3;  
14.      fib2 := tmp;  
15.    end if;  
16.  else if c<A[m]  
17.    if fib2=1 then return false  
18.    else  
19.      m := m-fib3;  
20.      fib2 := fib2 - fib3;  
21.      fib3 := fib3 - fib2;  
22.    end if;  
23.  else return true;  
24. until true;
```

# Complexity

---

- Worst-case:  $c$  is always in **the larger fraction** of  $A$ 
  - We roughly call once for  $n$ , once for  $2n/3$ , once for  $4n/9$ , ...
- Formula of Moivre-Binet: For large  $i$  ...

$$fib(i) \sim \left[ \frac{1}{\sqrt{5}} \left( \frac{1 + \sqrt{5}}{2} \right)^i \right] \sim k * 1.62^i$$

- We find  $i$  such that  $fib(i-1) \leq n \leq fib(i) \sim k * 1.62^i$
- In worst-case, we **make  $\sim i$  comparisons**
  - We break the array  $i$  times
- Since  $i = \log_{1.62}(n/k)$ , we are in  $O(\log(n))$

# Main message

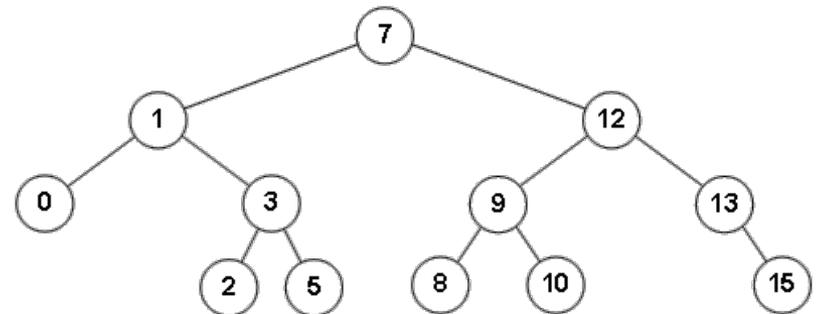

---

- If you break an array always in the middle, you can do this at most  $O(\log(n))$  times
- If you break an array always at  $1/3$  and  $2/3$ , you also can do this at most  $O(\log(n))$  times
- What if we break an array always at  $1/10 - 9/10$ ?
  - Wait a minute

# Searching without Math (sketch – details later)

---

- We actually can solve the search problem in  $O(\log(n))$  **using only comparisons** (no additions etc.)
- Transform A into a **balanced binary search tree**
  - At every node, the depth of the two subtrees differ by at most 1
  - At every node  $n$ , all values in the left (right) subtree are smaller (larger) than  $n$
- Search
  - Recursively compare  $c$  to node labels and descend left/right
  - Balanced bin-tree has depth  $O(\log(n))$
  - We need at most  $\log(n)$  comparisons – and nothing else

  - [Interpolation Search](#)
- Selecting in Unsorted Lists

# Interpolation Search

---

- Imagine you have a telephone book and search for „Zacharias“
- Will you open the book in the middle?
- We can **exploit additional knowledge** about the keys
- Interpolation Search: **Estimate** where  $c$  lies in  $A$  based on the **distribution of values in  $A$** 
  - Simple: Use max and min values in  $A$  and assume equal distribution
  - Complex: Approximation of real distribution (histograms, ...)

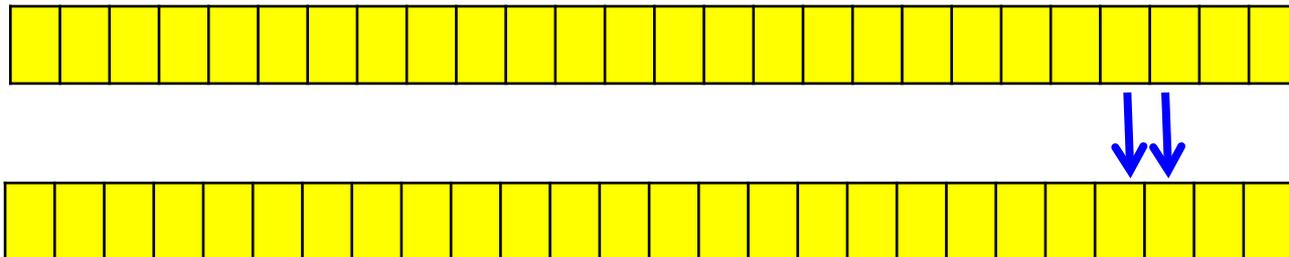

# Simple Interpolation Search

---

- Assume **equal distribution** – values within A are equally distributed in range [ A[1], A[n] ]
- Best guess for the **rank (position in A) of c**

$$\text{rank}(c) = f + (r - f) * \frac{c - A[f]}{a[r] - A[f]}$$

- Idea: Use  $m = \text{rank}(c)$  and proceed recursively
- Example: "Xylophon"

# Analysis

---

- On average, Interpolation Search on equally distributed data requires  $O(\log(\log(n)))$  comparison
  - Proof: See [OW94]
- But: Worst-case is  $O(n)$ 
  - If concrete distribution deviates heavily from expected distribution
  - E.g., A contains "aaa" and all other names > "Xylophon"
- Further disadvantage: In each phase, we perform  $\sim 4$  adds/subs and  $2 * \text{mults/divs}$ 
  - Assume this takes 12 cycles (1 mult/div = 4 cycles)
  - Binsearch requires  $2 * \text{adds/subs} + 1 * \text{shift} \sim 3$  cycles
  - Even for  $n = 2^{32} \sim 4E9$ , this yields  $12 * \log(\log(4E9)) \sim 72$  ops versus  $3 * \log(4E9) \sim 90$  ops – not that much difference

# Content of this Lecture

---

- Searching in Unsorted Lists
- Searching in Sorted Lists
- **Selecting in Unsorted Lists**
  - Naïve or clever

# Quantiles

---

- Recall: The **median** of a list is its middle value
  - Sort all values and take the one in the middle
- Generalization: **x%-quantiles**
  - Sort all values and take the value at **x% of all values**
  - Typical: 25, 75, 90, -quantiles
    - How long do 90% of all students need to obtain their degree?
  - The 25%, 50%, 75% are called **quartiles**
  - Median = 50%-quantile

# Selection Problem

---

- Definition

*The **selection problem** is to find the  $x\%$ -quantile of a set  $A$  of unsorted values*

- Solutions

- We can sort  $A$  and then access the quantile directly
- Thus,  $O(n \cdot \log(n))$  is easy
- It is easy to see that we have to look at least at each value once; thus, the **problem is in  $\Omega(n)$**
- Can we solve this problem in **linear time**?

# Observation and Example: Top-k Problem

---

- **Top-k**: Find the  $k$  largest values in  $A$
- For **constant  $k$** , a naïve solution is linear (and optimal)
  - repeat  $k$  times
  - go through  $A$  and find largest value  $v$ ;
  - remove  $v$  from  $A$ ;
  - return  $v$
  - Requires  $k * |A| = O(|A|)$  comparisons
- But if  $k = c * |A|$ , we are in  $O(c * |A| * |A|) = O(|A|^2)$ 
  - For any constant factor  $c$
  - We measure complexity in size of the input
  - It is decisive whether  **$c$  is part of the input** or not

# Selection Problem in Linear Time

---

- We sketch an algorithm which solves the selection problem **in linear time**
  - Actually, we solve the equivalent problem of returning the  $k$ 'th value in the sorted  $A$  (without sorting  $A$ )
- Interesting from a theoretical point-of-view
- Practically, the algorithm is of no importance because the **linear factor** gets enormously large
- It is instructive to see why (and where)

# Algorithm

- Recall **QuickSort**: Chose pivot element  $p$ , divide array wrt  $p$ , recursively sort both partitions using the same trick
- We reuse the idea: Chose pivot element  $p$ , divide array wrt  $p$ , recursively **select in the one partition** that must contain the  $k$ 'th element

```
1. func integer divide(A array;  
2.                       f,r integer) {  
3.     ...  
4.     while true  
5.       repeat  
6.         i := i+1;  
7.         until A[i]>=val;  
8.         repeat  
9.           j := j-1;  
10.          until A[j]<=val or j<i;  
11.          if i>j then  
12.            break while;  
13.          end if;  
14.          swap( A[i], A[j]);  
15.        end while;  
16.        swap( A[i], A[r]);  
17.        return i;  
18. }
```

```
1. func int quantile(A array;  
2.                   k, f, r int) {  
3.   if r<f then  
4.     return A[f];  
5.   end if;  
6.   pos := divide( A, f, r);  
7.   if (k ≤ pos-1) then  
8.     return quantile(A, k, f, pos-1);  
9.   else  
10.    return quantile(A, k-pos+1, pos, r);  
11.  end if;  
12. }
```

# Analysis

---

```
1. func int quantile(A array;
2.                   k, f, r int) {
3.   if r ≤ f then
4.     return A[f];
5.   end if;
6.   pos := divide( A, f, r);
7.   if (k ≤ pos-1) then
8.     return quantile(A, k, f, pos-1);
9.   else
10.    return quantile(A, k-pos+1, pos, r);
11.  end if;
12. }
```

- Worst-case: Assume arbitrarily badly chosen pivot elements
- pos always is r-1 (or f+1)
- Gives  $O(n^2)$
- Need to choose the pivot element p more carefully

# Choosing p

---

- Assume we can choose p such that we always continue with **at most q% of A** (with  $0 < q < 1$ )
  - I.e.,  $(1-q)\%$  of elements are discarded
- We perform at most  $T(n) = T(q*n) + c*n$  comparisons
  - $T(q*n)$  – recursive descent, with  $T(0)=0$
  - $c*n$  – function “divide”
- $T(n) = T(q*n) + c*n = T(q^2*n) + q*c*n + c*n = T(q^2*n) + (q+1)*c*n = T(q^3*n) + (q^2+q+1)*c*n = \dots$

$$T(n) = c * n * \sum_{i=0}^n q^i \leq c * n * \sum_{i=0}^{\infty} q^i = c * n * \frac{1}{1-q} = O(n)$$

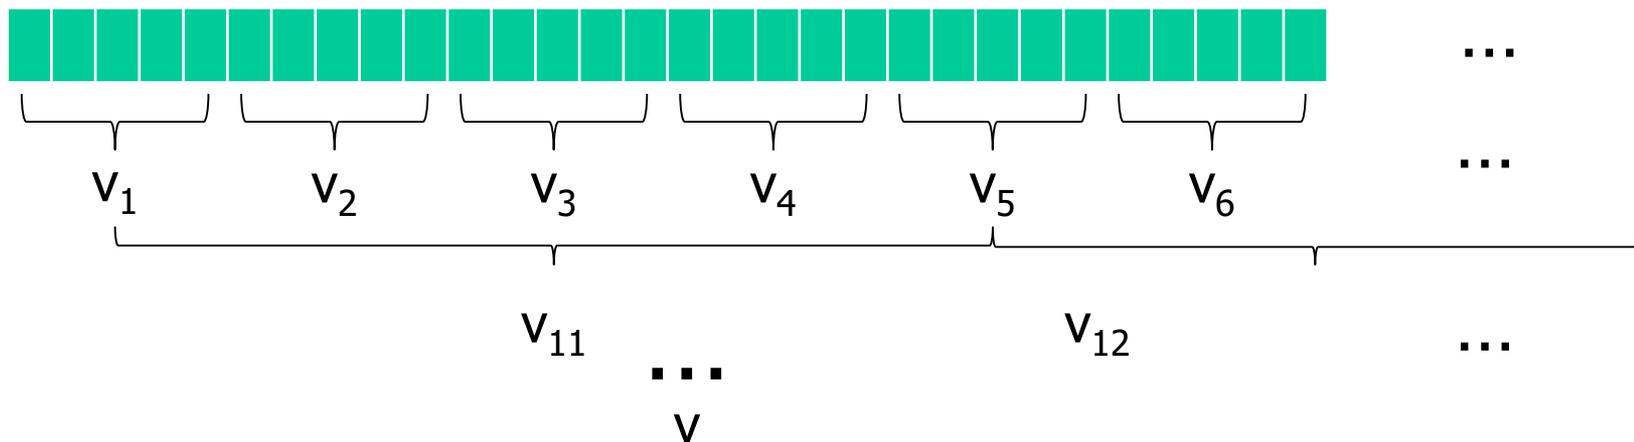

# Discussion

---

- Our algorithm has **worst-case complexity  $O(n)$**  when we manage to always reduce the array by a **fraction of its size**, no matter how large the fraction
  - This is not an average-case. We must always (not on average) cut some fraction of  $A$
- Eh – magic?
- No – follows from the way we defined complexity and what we consider as input
- Many operations become **“hidden” in the linear factor**
  - $q=0.9$ :  $c \cdot 10 \cdot n$
  - $q=0.99$ :  $c \cdot 100 \cdot n$
  - $q=0.999$ :  $c \cdot 1000 \cdot n$

# Median-of-Median

- How can we guarantee to always cut a fraction of  $A$ ?
- **Median-of-median** algorithm
  - Partition  $A$  in disjoint partitions of length 5
  - Compute the median  $v_i$  for each partition (with  $i < \text{floor}(n/5)$ )
  - Find the **median  $v$  of all  $v_i$**  by repeating this process
    - Hint:  $v$  will not be the exact median of  $A$  – but not too far away
  - Use  $v$  as pivot element for the quantile computation

# Complexity

---

- $O(n)$ : Run through A in partitions of length 5
- $O(1)$ : Find each median
  - Runtime of sorting a **list of length 5** does not depend on n
- The next iteration will work on only 20% of the input
- Since we always reduce the number of values to look at by 80%, this requires  **$O(n)$  time in total**
  - See previous result

# What Happens? (source: Wikipedia)

	12	15	11	2	9	5	0	7	3	21	44	40	1	18	20	32	19	35	37	39
	13	16	14	8	10	26	6	33	4	27	49	46	52	25	51	34	43	56	72	79
<b>Median</b>	17	23	24	28	29	30	31	36	42	47	50	55	58	60	63	65	66	67	81	83
	22	45	38	53	61	41	62	82	54	48	59	57	71	78	64	80	70	76	85	87
	96	95	94	86	89	69	68	97	73	92	74	88	99	84	75	90	77	93	98	91

- Median-of-median of a randomly permuted list 0..99
- For clarity, each 5-tuple is sorted (top-down) and all 5-tuples are sorted by median (left-right)
- Gray/white: Values with actually smaller/greater than med-of-med 47
- Blue: Range with certainly smaller / larger values

# Why Does this Help?

---

- We have  $\sim n/5$  first-level-medians  $v_i$
- $v$  (as median of medians) is **smaller than half of the  $v_i$**  and greater than the other half
  - The smaller and the larger set of medians both have  $\sim n/10$  values
- Each  $v_i$  itself is smaller than (and greater than) 2 values
- Since for the smaller (greater) medians this median itself is also smaller (greater) than  $v$ ,  $v$  is larger (smaller) than **at least  $3*n/10$  elements**
  - Border holds in both directions:  $v$  is in the range  $[3n/10...7n/10]$
